30th July 2019

#### Abstract

The Quadratic Knapsack Problem (QKP) is a well-known  $\mathcal{NP}$ -hard combinatorial optimisation problem, with many practical applications. We present a 'cut-and-branch' algorithm for the QKP, in which a cutting-plane phase is followed by a branch-and-bound phase. The cutting-plane phase is more sophisticated than the existing ones in the literature, incorporating several classes of cutting planes, a primal heuristic, and several rules for eliminating variables and constraints. Computational results show that the algorithm is competitive.

**Keywords:** knapsack problems, cutting planes, integer programming.

# 1 Introduction

The Quadratic Knapsack Problem (QKP) takes the form:

$$\max \sum_{i=1}^{n} \sum_{j=1}^{n} q_{ij} x_i x_j$$
s.t. 
$$\sum_{i=1}^{n} w_i x_i \le c$$
 (1) [eq:knapsack] 
$$x \in \{0,1\}^n,$$
 (2) [eq:x-bin]

where n is the number of *items*, c is the (positive and integral) capacity, the  $w_i$  are the (positive and integral) weights, and the  $q_{ij}$  are the (integral)

profits. The QKP includes as a special case the standard (linear) knapsack problem (KP), which is obtained when  $q_{ij} = 0$  for all  $i \neq j$ .

The QKP, introduced in Gallo *et al.* [12], has applications in finance, logistics and telecommunications. It is  $\mathcal{NP}$ -hard in the strong sense, by reduction from the maximum clique problem [5]. For good surveys of applications, bounding procedures, heuristics and exact algorithms, see [18, 21]. At present, the most effective exact algorithms are the ones in [5, 22], which are based on Lagrangian relaxation.

In this paper, we present a 'cut-and-branch' framework for the QKP. This framework incorporates four families of cutting planes, a primal heuristic, and several rules for eliminating variables and constraints. We also present the results of some extensive computational experiments. As well as testing our algorithm on standard QKP instances, such as those used in [5, 22], we also test it on the so-called *hidden clique* instances, which were recently shown to be extremely challenging for existing QKP algorithms [26]. Our computational results show that our algorithm is competitive with the best existing algorithms.

The paper is structured as follows. In Section 2, we review the relevant literature. In Section 3, we present several *separation routines* (i.e., routines for generating cutting planes). In Section 4, we describe the other components of the cut-and-branch algorithm. The computational results are given in Section 5. Finally, some concluding remarks are made in Section 6.

Throughout the paper, we assume that the reader is familiar with the basics of integer programming, including cutting planes, branch-and-bound and separation algorithms (see [29] for an introduction). We also use the following notation: N denotes  $\{1, \ldots, n\}$ , E denotes  $\{S \subset N : |S| = 2\}$ , and E denotes the set of all ordered pairs E with E and E and E and E and E are think of E as being a set of nodes, E as being the edge set of a complete undirected graph, and E as being the arc set of a complete directed graph.)

# 2 Literature Review

(se:lit) Since the literature on the QKP is vast, we review here only results that are of direct relevance, and refer the reader to the surveys [18,21].

### 2.1 Standard formulation of the QKP

Using a standard construction [13], one can formulate the QKP as a 0-1 linear program (0-1 LP). Let the x variables be defined as above. For all  $\{i, j\} \in E$ , let  $y_{ij}$  be an additional binary variable, representing the product

 $x_i x_j$ . The formulation is then:

This formulation is used in [2-4,11,15]. We will call the inequalities (4) and (5) trivial inequalities.

# 2.2 Cutting planes for the KP

The convex hull of vectors  $x \in \{0,1\}^n$  satisfying the knapsack constraint (1) is called the *knapsack polytope*, and has been studied in depth (see, e.g., [1,14,17,19,27,28]).

The most well-known valid inequalities for the knapsack polytope are the lifted cover (LC) inequalities. A set  $C \subset N$  is called a cover if  $\sum_{i \in C} w_i > c$ . The cover is minimal if no proper subset of it is a cover. Balas [1] and Wolsey [28] showed that, given any minimal cover  $C \subset N$ , there exists at least one facet-defining LC inequality of the form:

$$\sum_{i \in C} x_i + \sum_{i \in N \setminus C} \alpha_i x_i \le |C| - 1$$

with  $\alpha_i \geq 0$  for all  $i \in N \setminus C$ .

Balas [1] defined a simple family of (not necessarily facet-defining) LC inequalities. For a given cover C, let E(C) denote the set of items in  $N \setminus C$  that weigh at least as much as the heaviest item in C. Then one can simply set  $\alpha_i$  to 1 if  $i \in E(C)$ , and to 0 otherwise. The resulting LC inequality is called an *extended* cover (EC) inequality.

### 2.3 Cutting planes for the QKP

The convex hull of pairs  $(x, y) \in \{0, 1\}^{n+E}$  satisfying (1), (4) and (5) is called the quadratic knapsack polytope [15,23,24]. One key class of valid inequalities, mentioned in [2,15], is obtained via the reformulation-linearization technique (RLT) of Sherali & Adams [25]. Take the knapsack constraint (1) and multiply it by a variable  $x_k$  or by its complement  $1 - x_k$ , and then replace any products of the form  $x_i x_k$  with  $y_{ij}$ . This yields the following 2n inequalities:

$$\sum_{i \in N \setminus \{k\}} w_i y_{ik} \le (c - w_k) x_k \qquad (k \in N)$$
 (6) eq:RLT1

$$\sum_{i \in N \setminus \{k\}} w_i(x_i - y_{ik}) \le c - cx_k \quad (k \in N). \tag{7}$$

We will call these RLT inequalities.

It is pointed out in [15] that one can apply the RLT to any valid inequality for the knapsack polytope, not only the knapsack constraint itself. So, for example, given any LC inequality for the KP, one can derive 2n distinct valid inequalities for the QKP. It is shown in [11] that, if the original inequality defines a facet of the knapsack polytope, then the resulting inequalities define facets of the quadratic knapsack polytope, under mild conditions.

Another important class of inequalities for the QKP are the following *triangle* inequalities:

$$x_i + x_j + x_k \le y_{ij} + y_{ik} + y_{jk} + 1$$
 ({i, j, k}  $\subset N$ ) (8) eq:tri1  
 $y_{ik} + y_{jk} \le x_k + y_{ij}$  ({i, j}  $\in E, k \in N \setminus \{i, j\}$ ). (9) eq:tri2

These inequalities are well known in the literature on 0-1 quadratic problems; see, e.g., [8,20]. They were applied to the QKP in [2,15].

Finally, we mention the *cover-tree* (CT) inequalities [16]. Given a minimal cover C, let  $K_C$  be a complete graph with vertex set C, and let T be the set of edges in a spanning tree in  $K_C$ . For all  $i \in C$ , let  $d_i$  denote the degree of i in the tree. Then, the CT inequality takes the form:

$$\sum_{\{i,j\}\in T} y_{ij} \le \sum_{i\in C} (d_i - 1)x_i. \tag{10} \text{ eq:CT}$$

Conditions for these to define facets are given in [23, 24]. Some weaker inequalities, called *matching-cover* inequalities, were given in [15].

# 2.4 Algorithms for the QKP

Finally, we mention the main exact and heuristic algorithms for the QKP.

The exact algorithms are all of branch-and-bound type, the chief difference being the procedure that is used to compute the upper bounds at each node. In [12], the upper bounds are obtained by solving KPs. In [3,5,6], they are obtained via Lagrangian relaxation. In [2], they are obtained with a cutting-plane algorithm, that uses the inequalities (1), (4), (5), (6) and (8). In [4], they are based on a compact linearisation with only O(n) variables.

Broadly speaking, the algorithm in [5] is the most effective, although the algorithms in [3,4] are competitive for very sparse instances (i.e., instances in which the majority of the  $q_{ij}$  are zero). Pisinger *et al.* [22] presented an enhanced version of the algorithm in [5]. The idea is to apply several procedures for eliminating variables, and thereby reduce the size of the problem, before calling the algorithm in [5].

As for heuristics, some good early examples can be found in [2, 6, 12]. More recently, two of the present authors presented a new heuristic [10], which significantly outperformed the ones mentioned. It is based on the construction of an initial solution via dynamic programming, followed by

the local search procedure from [12]. We will use this heuristic at the start of our cut-and-branch algorithm, to obtain an initial lower bound.

#### 3 Separation Routines

 $\langle \mathtt{se:separation} \rangle$  Our algorithm uses four different families of valid inequalities as cutting planes: the RLT inequalities (6), (7), the triangle inequalities (8), (9), the CT inequalities (10), and the inequalities obtained by applying the RLT to LC inequalities, which we call "RLT-LC" inequalities. In this section, we describe our separation routines for these four families. Throughout, we let  $(x^*, y^*)$  denote the LP solution to be separated, and we assume that  $(x^*, y^*) \in [0, 1]^{N+E}$ .

#### 3.1 RLT inequalities

Since there are only 2n RLT inequalities, and each one has only  $\mathcal{O}(n)$  nonzero coefficients, the RLT separation problem can be solved exactly in  $\mathcal{O}(n^2)$ time by mere enumeration. It often happens that there exist several violated RLT inequalities. In that case, we add to the LP only the most-violated inequality of the form (6), if any, and the most-violated inequality of the form (7), if any. This is to prevent the LP from becoming too large.

#### 3.2 Triangle inequalities

Since there are  $\mathcal{O}(n^3)$  triangle inequalities, and each one has only  $\mathcal{O}(1)$ non-zero coefficients, the triangle separation problem can be solved exactly in  $\mathcal{O}(n^3)$  time by enumeration. Again, to prevent the LP from becoming too large, we add to the LP only  $\mathcal{O}(n^2)$  violated inequalities in any given cutting-plane iteration. Specifically, for a given  $\{i,j\} \in E$ , we add to the LP only the most-violated triangle inequality of the form (8), if any, and the most-violated triangle inequality of the form (9), if any.

#### 3.3 Linearisation operator

For our remaining separation routines, we have found it helpful to begin by mapping  $(x^*, y^*)$  onto  $[0, 1]^N$ , i.e., onto the space of the standard (linear) knapsack polytope. This is done by applying one of the following three mappings:

- Just take  $x^*$  itself.
- For each  $i \in N$  such that  $x_i^* > 0$ , create a point  $\bar{x}^i \in [0,1]^N$  by setting  $\bar{x}_i^i := x_i^*$  and setting  $\bar{x}_i^i := y_{ij}^*/x_i^*$  for all  $j \in N \setminus \{i\}$ .
- For each  $i \in N$  such that  $x_i^* < 1$ , create a point  $\tilde{x}^i \in [0,1]^N$  by setting  $\tilde{x}_i^i := x_i^*$  and setting  $\tilde{x}_j^i := (x_j^* y_{ij}^*)/(1 x_i^*)$  for all  $j \in N \setminus \{i\}$ .

In this way, we obtain up to 2n+1 points in the x-space. The idea underlying the second and third steps is that, in a feasible QKP solution,  $x_j = y_{ij}/x_i$  when  $x_i = 1$ , and  $(x_j - y_{ij})/(1 - x_i)$  when  $x_i = 0$ . So there is a chance that at least some of the points will lie close to the boundary of the knapsack polytope.

We call this whole approach the *linearisation operator*. Note that it takes  $\mathcal{O}(n^2)$  time. The following two subsections explain how it is used.

# 3.4 CT inequalities

A simple separation heuristic for the CT inequalities, based on building the tree greedily, is presented in [16]. We, however, use a completely different heuristic, in which we first generate a list of candidate covers, and then compute the best tree for each candidate.

To generate the covers, one can simply take each of the fractional points generated by the linearisation operator, and feed it into any exact or heuristic separation algorithm for cover inequalities. It is important to note that, even if a cover inequality generated in this way is not violated, the associated cover could still lead to a violated CT inequality.

Now, the separation problem for CT inequalities, for a *fixed* minimal cover C, is easy. Re-write the CT inequality as:

$$\sum_{\{i,j\} \in T} (x_i + x_j - y_{ij}) \ge \sum_{i \in C} x_i.$$

There exists a violated CT inequality for the given cover C, if and only if there exists a tree  $T^*$  such that:

$$\sum_{\{i,j\}\in T} (x_i^* + x_j^* - y_{ij}^*) < \sum_{i\in C} x_i^*. \tag{11} eq:separation$$

Since the right-hand side of (11) is a constant for fixed C and  $x^*$ , it suffices to find a tree  $T^*$  that minimises the left-hand side. This can be done by finding a minimum weight spanning tree in the graph  $G_C$ , where the weight of each edge  $\{i,j\}$  is set to  $y_{ij}^* - x_i^* - x_j^*$ . This spanning tree can be found in  $\mathcal{O}(|C|^2)$  time using any of several well-known algorithms.

To generate the covers, we use the separation heuristic in [7], which runs in  $\mathcal{O}(n \log n)$  time. Since the linearisation operator creates  $\mathcal{O}(n)$  fractional points, the time taken by this scheme is  $\mathcal{O}(n^2 \log n)$  to create the covers, plus  $\mathcal{O}(n^3)$  for the spanning tree computations. All violated CT inequalities found, if any, are added to the LP.

# 3.5 RLT-LC inequalities

Finally, we consider separation for the RLT-LC inequalities. One simple heuristic is to solve the separation problem for standard LC inequalities, using  $x^*$  as input, and then check the 2n corresponding RLT-LC inequalities for violation. The running time is then determined by the time taken by the LC separator, together with the time taken to check the RLT-LC inequalities, which is  $\mathcal{O}(n^2)$ .

A more interesting, but more time-consuming, heuristic is the following: take each of the points created by the linearisation operator, and feed it into an LC separator. Then, for each of the LC inequalities created in this way, check the 2n corresponding RLT-LC inequalities for violation. This increases the running time by a factor of n.

We found that, in the QKP context, it was usually enough to use only the inequalities obtained by applying the RLT to EC inequalities. We call the resulting inequalities RLT-EC inequalities. In our separation scheme, we feed the points from the linearisation operator into the EC separation heuristic described in Subsection 3.3 of [17]. That EC heuristic runs in  $\mathcal{O}(n^2)$  time, which means that our RLT-EC heuristic runs in  $\mathcal{O}(n^3)$  time. All violated RLT-EC inequalities found, if any, are added to the LP.

# 4 The Cut-and-Branch Algorithm

(se:CAB) As stated in the introduction, we have devised a cut-and-branch algorithm for the QKP, which uses the separation routines described in the previous section as subroutines. A high-level description of our cut-and-branch algorithm is as follows:

- 1. Run the heuristic described in [10], yielding an initial lower bound L.
- 2. Solve an initial LP relaxation, and let U be the resulting upper bound.
- 3. Call the LP-based primal heuristic. If an improved primal solution is found, update L.
- 4. Call some separation routines. If any violated inequalities are found, go to step 5. Else go to step 12.
- 5. Add the inequalities to the LP and re-optimise via dual simplex.
- 6. If the upper bound has decreased, update U.
- 7. Call the LP-based primal heuristic. If an improved primal solution is found, update L.
- 8. If L = |U|, output the optimal solution and stop.
- 9. If (some y variables can be eliminated), then mark them for elimination (but don't actually delete them).
- 10. Delete any cutting planes whose slack exceeds some threshold.
- 11. Go to step 4.
- 12. Delete any cutting planes whose dual price is zero.
- 13. Eliminate all marked y variables from the formulation.

14. Change all x variables to binary and solve the resulting 0-1 LP via branchand-bound.

The key components of this algorithm are described in more detail in the following subsections. As in the previous section,  $(x^*, y^*)$  denotes the optimal solution to the current LP relaxation.

### Initial LP relaxation

The initial LP relaxation consists of the objective function (3) and the constraints (1), (4) and (5) (plus non-negativity as usual). We do not include the upper bounds of 1 on the variables in the relaxation, either explicitly or implicitly, since (a) they are implied by the constraints (4), (5) and nonnegativity, and (b) their inclusion would substantially increase the amount of degeneracy present in the LP.

#### Separation order 4.2

 $\langle \mathtt{sub:order} \rangle$  We use four different classes of inequalities in the cutting-plane phase of our algorithm: RLT, triangle, CT and RLT-EC inequalities. Of these, the triangle inequalities are the sparsest, but they also tend to create primal degeneracy. Moreover, the CT and RLT-EC inequalities are being separated heuristically rather than exactly. For these reasons, the order in which the inequalities are separated can substantially affect the number of cuttingplane iterations, the time taken to solve each LP, the quality of the bounds obtained, the number of eliminated y variables, and the total computing

> In some computational experiments, reported in Subsection 5.2, we tried several different combinations and orderings of the separation routines, in order to choose the best. In the end, we decided to call RLT separation first. Then, if no violated RLT inequalities are found, we call triangle separation. If that fails, we call RLT-EC separation. Finally, if that fails too, we call CT separation.

#### 4.3 Cut deletion

To prevent the LP from getting too large, we delete some cutting planes after each re-optimisation of the LP. More precisely, we delete all RLT, triangle, CT and RLT-EC inequalities whose slack exceeds a certain threshold. We do not delete the constraints (1), (4) or (5), however, since those are part of the 0-1 LP formulation itself.

#### 4.4 LP-based primal heuristic

Each time the current LP relaxation is solved, we call a primal heuristic that attempts to construct a good QKP solution using the information contained in the LP solution. This is a simple greedy heuristic that proceeds as follows. Sort the items in N in non-increasing order of  $x^*$  value. Start with an empty knapsack, and then examine each item in the sorted list. If there is sufficient remaining space in the knapsack for the item, then place the item in the knapsack.

For example, suppose that n = 5, c = 100,  $w = (50, 40, 30, 20, 10)^T$  and  $x^* = (0.6, 0.5, 0.2, 0.4, 0.3)^T$ . The sorted list of items is (1, 2, 4, 5, 3). Initially, the available capacity is 100, so we insert item 1. The remaining capacity is 50, so we insert item 2. The remaining capacity is 10, so we cannot insert item 4. We can however insert item 5. The knapsack is now full, so we terminate with items 1, 2 and 5 in the knapsack.

# 4.5 Reduction procedures

After each major iteration of the cutting-plane algorithm, it helps to apply reduction procedures, that eliminate variables and constraints from the LP without causing any optimal solutions to be lost. One simple reduction procedure, usually attributed to Crowder et al. [7], is reduced-cost fixing: any variable that takes a zero value at  $(x^*, y^*)$ , and has a reduced cost larger than U - L, can be permanently fixed to 0, and therefore removed from the problem. Our reduction procedures are more sophisticated.

Observe that, at any stage of the cutting-plane phase, the LP relaxation will always include the following inequalities for each pair  $\{i, j\} \in E$ :

$$y_{ij} \le x_i$$
 (12) eq:bit1

$$y_{ij} \le x_j$$
 (13) eq:bit2

$$y_{ij} \ge x_i + x_j - 1. \tag{14}$$

For any pair  $\{i, j\} \in E$ , we let  $\lambda_{ij}^1$ ,  $\lambda_{ij}^2$  and  $\lambda_{ij}^3$  denote the dual prices of the constraints (12), (13) and (14), respectively. Also, for any  $i \in N$ , we let  $\rho_i$  denote the reduced cost of  $x_i$ . Finally, for any pair  $\{i, j\} \in E$ , we let  $\phi_{ij}$  be the reduced cost of  $y_{ij}$ .

Our reduction procedure is then based on the following three lemmas:

**Lemma 1** If, for some  $\{i, j\} \in E$ , we have  $\rho_i + \rho_j + \phi_{ij} > U - L$ , then we can permanently remove  $y_{ij}$  from the problem (or, equivalently, fix  $y_{ij}$  to zero). Moreover, we can replace the constraints (12)–(14) with the single constraint  $x_i + x_j \leq 1$ .

**Proof.** From the definition of reduced costs, it follows that, if we added to the LP the constraints  $x_i \geq 1$ ,  $x_j \geq 1$  and  $y_{ij} \geq 1$ , then the optimal profit would decrease by at least  $\rho_i + \rho_j + \phi_{ij}$ . Under the stated assumption, the profit would drop below L, thus showing that no optimal solution of the QKP could have  $x_i = x_j = y_{ij} = 1$ . As a result,  $y_{ij}$  must be zero in an optimal QKP solution. Setting  $y_{ij}$  to 0 and simplifying the constraints (12)–(14) yields the constraint  $x_i + x_j \leq 1$ .

**Lemma 2** If, for some  $(i, j) \in A$ , we have  $\rho_i + \lambda_{ij}^1 > U - L$ , then we can replace  $y_{ij}$  with  $x_i$  everywhere in the formulation. Moreover, we can replace the constraints (12)–(14) with the constraints  $x_i \leq x_j \leq 1$ .

**Proof.** From the definition of reduced costs and dual prices, it follows that, if we added to the LP the constraints  $x_i \geq 1$  and  $y_{ij} \leq x_i - 1$ , then the optimal profit would decrease by at least  $\rho_i + \lambda_{ij}^1$ . Under the stated assumption, the profit would drop below L, thus showing that no optimal solution could have  $x_i = 1$ ,  $x_j = 0$  and  $y_{ij} = 0$ . As a result,  $y_{ij}$  must equal  $x_i$  in an optimal solution. Setting  $y_{ij}$  to  $x_i$  and simplifying (12)–(14) yields  $x_i \leq x_j \leq 1$ .

**Lemma 3** If, for some pair  $\{i, j\} \in E$ , we have  $\lambda_{ij}^3 > U - L$ , then we can replace  $y_{ij}$  with  $x_i + x_j - 1$  everywhere in the formulation. In particular, the constraints (12)–(14) can be replaced with the constraints  $x_i \leq 1$ ,  $x_j \leq 1$  and  $x_i + x_j \geq 1$ .

**Proof.** From the definition of dual prices, it follows that, if we added to the LP the constraint  $y_{ij} \geq x_i + x_j$ , then the optimal profit would decrease by at least  $\lambda_{ij}^3$ . Under the stated assumption, the profit would drop below L, thus showing that no optimal solution could have  $y_{ij} = x_i + x_j$ . As a result,  $y_{ij}$  must equal  $x_i + x_j - 1$  in an optimal solution. Setting  $y_{ij}$  to  $x_i + x_j - 1$  and simplifying (12)–(14) yields  $x_i \leq 1$ ,  $x_j \leq 1$  and  $x_i + x_j \geq 1$ .

The computational results given later show that a substantial proportion of the y variables can be eliminated in this way. Moreover, even a relatively small amount of elimination can be highly beneficial in the branch-and-bound phase, because, each time a y variable is eliminated, the corresponding constraints (12)–(14) are eliminated and/or simplified as well.

### 4.6 Final 0-1 LP formulation

Once the cutting-plane algorithm has terminated and y variables have been eliminated, we take the LP, re-optimise it, and then delete all RLT, triangle, CT and RLT-EC inequalities that have zero dual price. This is to make the final LP as small as possible, while maintaining the quality of the upper bound. Then we add the condition that all variables must be binary, yielding a 0-1 LP formulation of the QKP. This formulation is then fed into a branch-and-bound solver.

# 5 Computational Results

(se:results) In this section, we present our computational results. All our routines were coded in the C programming language and compiled with gcc 4.6. All the

results were obtained by running our code on a single cluster node of the super computer of Compute Canada<sup>1</sup> with processor at 2.26 GHz and 24 GB of RAM while requiring only 8 GB for our code. The LP relaxations and the final 0-1 LPs were solved with the simplex and MIP solvers of CPLEX version 12.5.

### 5.1 Test instances

The standard scheme for creating test instances for the QKP is the one proposed by Gallo *et al.* [12]. For a given value of n, each weight  $w_i$  is an integer uniformly distributed between 1 and 100. The knapsack capacity c is an integer uniformly distributed between 50 and  $\sum_{i \in N} w_i$ . Finally, for a given choice of *density parameter*  $\Delta$ %, each profit term  $q_{ij}$  is set to zero with probability  $(100 - \Delta)$ %, and set to an integer uniformly distributed between 1 and 100 with probability  $\Delta$ %.

For each value of  $n \in \{10, 20, ..., 100\}$  and  $\Delta\%$ , we created 10 random instances. We call the resulting 400 instance 'small". To test the limits of our algorithm, we also created 10 random instances for each combination of  $n \in \{50, 100, 150, 200, ..., 800\}$  and  $\Delta \in \{25\%, 50\%, 75\%, 100\%\}$ . This makes an additional 640 instances, which we call "large".

To further test the limits of our procedure, we also created some "planted clique" (PC) instances. Instances of this type were recently introduced by Schauer [26], who showed that they are very challenging for existing exact and heuristic QKP algorithms. For a given n, one generates a random (so-called Erdős-Rényi) graph, in which each edge is present with probability 1/2. One then "plants" a clique in it, by selecting a random set of  $\lfloor n \rfloor$  nodes, and adding edges, if necessary, so that those nodes form a clique. The knapsack capacity is then set to  $\lfloor n \rfloor$ . The weight of each vertex is 1, its linear profit is 0 and the quadratic profit is 1 whenever an edge occurs in the graph, otherwise it is 0. The optimal solution value is then almost surely  $\frac{1}{2} \lfloor n \rfloor (\lfloor n \rfloor - 1)$ . We generated 10 PC instances for each value of  $n \in \{20, 40, 60, \ldots, 200\}$ , making 100 in total.

### 5.2 The cutting-plane algorithm

 $\langle \mathtt{sub:cpa} \rangle$  To begin with, we were interested in determining the effect that the separation order has on the performance of the cutting-plane algorithm. To do this, we let the cutting-plane algorithm run to completion, without terminating even if the condition  $L = \lfloor U \rfloor$  held. The results obtained on the "small" instances are presented in Table 1 and Table 2. In these two tables, we present the results for the four most promising orderings of the separation routines. The values in the tables are the averages over 10 instances.

<sup>&</sup>lt;sup>1</sup>www.computecanada.ca

For each ordering, we present the percentage gap between the upper bound and the optimum, the time needed to compute that bound, in seconds, and the percentage of y variables eliminated from the problem.

It can be seen from the results of these tables that our cutting-plane algorithm can consistently produce upper bounds within 1% of optimality, in reasonable computing times. The number of y variables reduced is also quite remarkable. It is hard to say anything conclusive about the effect of the separation order on the quality of the results. In the end, we settled on the fourth separation order, as mentioned in Subsection 4.2.

### 5.3 Cut-and-branch

Next, we investigated the performance of our cut-and-branch algorithm on the "large" instances. The results are shown in Table 3. In this table, we report the percentage gap of the upper bound found by our cutting-plane algorithm, the time taken to compute this upper bound, the percentage gap of the lower bound, the number of branch-and-bound nodes, and the total computing time. The number of y variables reduced reported here is the average over the instances that were not already solved during the cutting-plane phase. All the other values are averages over 10 instances. For the branch-and-bound phase, we used the standard MIP solver of CPLEX, with default settings, except that all internal cutting-plane generators were switched off.

The results in Table 3 are interesting for several reasons. First, the upper bounds found by our algorithm are within 0.5% of optimality for almost all instances. Second, the primal heuristic conistently produces solutions within 0.1% of optimality. These tight bounds lead to a significant proportion of y variables being eliminated. This in turn eases the burden on the branch-and-bound solver, as evidenced by the relatively low number of branch-and-bound nodes required. Finally, looking at the last column of Table 3, it is apparent that all 640 large instances could be solved within a five-hour time limit. In fact, more than 50% of the instances were solved within one hour. Overall, it is clear that our algorithm is capable of solving QKP instances with up to 800 items, regardless of their density, within a reasonable amount time.

### 5.4 Planted clique instances

Finally, we consider the planted clique (PC) instances. Figure 1 shows the upper and lower bound gaps, the CPU time at the root node, i.e., after the cutting-plane phase, and the CPU time at the end of the whole algorithm. It can be seen in Figure 1a that the upper bound gaps obtained by our algorithm are of great quality (almost always zero in fact). The lower bounds on the other hand are very poor. This is however to be expected, since the

Table 3: Cut-and-branch results

weakness of existing QPK heuristics for PC instances was already noted in [26].

As for the branch-and-bound phase, Figure 1b shows that it was very time consuming for these instances. This is almost certainly due to the poor lower bounds. Despite this, however, our algorithm is capable of finding the optimal solution to PC instances with up to 200 items within five hours. This can be seen as a milestone, since the state-of-the-art algorithm of Caprara et al. [5] failed to do so, according to [26].

# 6 Conclusion

 $\langle \mathtt{se:end} \rangle$ 

We have presented a new exact 'cut-and-branch' algorithm for the QKP. Our algorithm incorporates a cutting-plane phase, primal heuristics, rules for eliminating variables and constraints, and a branch-and-bound phase. Our computational results show that our algorithm is capable of solving much larger "standard" QKP instances that those solvable by the algorithm of Caprara et al. [5]. More precisely, our algorithm is capable of solving standard QKP instances with up 800 items within a five hour time limit. For the much more difficult planted-clique instances, our proposed algorithm is able to find the optimal solution for instances with up to 200 items within five hours. Moreover, for these instances, the upper bounds found by the cutting-plane phase are almost always optimal.

For future research, one could of course derive new inequalities and/or separation algorithms (see for example [9]) and implement a full branch-and-cut algorithm. It would also be very worthwhile trying to use an "aggressive reduction" scheme similar to that of Pisinger et al. [22] as a "pre-processor", and then running our algorithm on the reduced problem. We believe that this approach would enable one to solve even larger instances.
